Nonequilibrium Quantum Phase Transitions in the Ising Model

V. M. Bastidas, C. Emary, G. Schaller, and T. Brandes
Institut für Theoretische Physik, Technische Universität Berlin, Hardenbergstr. 36, 10623 Berlin, Germany

We establish a set of nonequilibrium quantum phase transitions in the Ising model driven under monochromatic nonadiabatic modulation of the transverse field. We show that the system exhibits a set of sideband quantum phase transitions as a consequence of multiphotonic resonances. The nonequilibrium quantum phases correspond to states which are synchronized with the external control in the long-time dynamics.

One of the more intriguing hallmarks of many-body systems is that at zero temperature quantum fluctuations can drive the system to a drastic change of state, commonly known as a quantum phase transition (QPT). A paradigmatic model for QPTs is the one-dimensional Ising model [1]. Recently, experimental realizations of one-dimensional spin chains have been suggested, where a quantum simulation of the system close to the phase transition is possible, and a wide freedom on the control of the parameters is achieved [2-6]. The quantum control of many-body systems by a driving field has attracted considerable interest both theoretical and experimental with workers from very different communities beginning to look at driven models [7-10]. The possibility to manipulate the quantum state of a system by means of a classical external control allows one to explore novel states of matter and effective interactions which are absent in equilibrium [15-18]. In the presence of an external control, quantum resonances and symmetries play an important role [19-22]. In particular, as a consequence of a generalized parity in the extended Hilbert space [10], the effect of periodic driving the tunneling can be slow down or totally suppressed in a perfect coherent way, a phenomenon commonly referred to as coherent destruction of tunneling (CDT) [23,24]. Rather recently, the extension of this concept to many-body systems has been addressed in the context of the Mott-superfluid transition in ultracold systems either theoretically [12] as well as experimentally [14], and in a two-mode Bose-Hubbard model with time-dependent self-interaction strength [10].

The dynamics of one-dimensional spin chains has been addressed extensively when the system is driven slowly through the critical point [21,26], where there is a diverging relaxation time and correlation length, and the dynamics cannot be adiabatic in the thermodynamic limit. As a consequence of this, the final state of the system consists of ordered domains whose finite size depend upon the velocity of the parameter variation [28]. A nontrivial oscillation of the magnetization [29] and the connection between symmetry and CDT [30] has been investigated in a finite size periodically-driven Ising model. Furthermore, under the effect of a nonadiabatic external control of the transverse field, the Ising chain exhibits dynamical freezing of the response [31,32], and synchronization with the external driving in the asymptotic dynamics as a consequence of destructive interference in time [33].

Our aim in this paper is to describe the nonequilibrium behaviour of a one-dimensional Ising model under the effect of a nonadiabatic monochromatic transverse field from the perspective of quantum criticality. In particular, we describe the dynamics by means of an effective Hamiltonian which simulates the dynamics of an undriven system. We show that in the asymptotic dynamics the nonequilibrium quantum phases correspond to states of the system which are synchronized with the driving. In contrast to previous works [31,33], however, we describe the role of many-body CDT in the critical behaviour by investigating signatures of criticality both in the laboratory frame as well as in the rotating frame.

The paper is organized as follows: In sec. I we discuss the equations of motion and describe quantum resonances by considering the excitation spectrum of the undriven system. In sec. II we describe the physics of the system by means of the rotating wave approximation and discuss signatures of criticality based on the description of the quasienergy dispersion and CDT. In sect. III we describe the quantum dynamics in the laboratory frame by considering the quasiparticle evolution of the system when is initialized in a paramagnetic ground state. Furthermore, we study signatures of criticality by considering cycle-averaged expectation values of physical observables. Finally, discussion of the results is presented in sec. IV.

I. QUANTUM RESONANCES IN THE ISING MODEL.

The periodically-driven transverse Ising model describes the dynamics of N interacting two-level systems in a time-dependent transverse local field [31,33]

\[ H(t) = -g(t) \sum_{i=1}^{N} \sigma_i^x - J \sum_{i=1}^{N} \sigma_i^z \sigma_{i+1}^z, \tag{1} \]

where \( \sigma_i^a \) are Pauli matrices at the \( i \)th site and we assume periodic boundary conditions \( \sigma_1^a = \sigma_{N+1}^a \) for
\( \alpha \in \{x, y, z\} \). In the following we shall consider \( J > 0 \), and a monochromatic modulation of the transverse field with a static contribution \( g(t) = g_0 + g_1 \cos(\Omega t) \). Via a Kramers-Wannier self-duality transformation \([34, 35]\), and after a spin rotation, it is possible to map Hamiltonian Eq. \( \mathbf{1} \) into a dual periodically-driven Ising model
\[
\hat{H}_D(t) = -g(t) \sum_{i=1}^{N} \tau_i^z \tau_{i+1}^z - J \sum_{i=1}^{N} \tau_i^\alpha,
\]
where \( \tau_i^z \tau_{i+1}^z = \sigma_i^z \), and \( \sigma_i^z \sigma_{i+1}^z = \tau_i^\alpha \). Therefore, the study of the nonequilibrium QPT in the Hamiltonian Eq. \( \mathbf{1} \), allows one to get a physical picture of the corresponding QPT in the dual model where the spin-spin interaction is time-dependent.

Associated with the Hamiltonian Eq. \( \mathbf{1} \) is a conserved parity \( \Pi \), such that \( [\hat{H}(t), \Pi] = 0 \), which is given by
\[
\Pi = \bigotimes_{i=1}^{N} \sigma_i^z.
\]
In the thermodynamic limit \( N \to \infty \), the undriven Ising model (\( g_1 = 0 \)) exhibits a second-order QPT at \( g_0^c = J \) from a symmetric paramagnetic phase (\( g_0 > J \)) to a symmetry-broken ferromagnetic phase (\( g_0 < J \)[1]). Our aim in this paper is to study the new aspects of criticality under the effect of driving.

In this section we provide the basics on the formalism used to describe the time-dependent Ising model. In particular, we find a resonance condition related to m-photon processes under the effect of driving.

A. The dynamic Bogoliubov de Gennes equations

In this paper we consider the restriction of the Hamiltonian Eq. \( \mathbf{1} \) to the subspace with even (+) number of fermionic quasiparticles (see appendix A). After a Jordan-Wigner transformation and a discrete Fourier transform of Hamiltonian Eq. \( \mathbf{1} \) we obtain
\[
\hat{H}(t) = \sum_{k>0} \left[ 2 (g(t) - J \cos(k)) (c_k^\dagger c_k + c_{-k}^\dagger c_{-k}) - 2g(t) \right] + \sum_{k>0} 2J \sin(k) (c_k^\dagger c_{-k} + c_{-k}^\dagger c_k) = \sum_{k>0} \hat{H}_k(t),
\]
where \( c_k^\dagger \) and \( c_k \) are fermionic operators \([1]\). For finite size \( N \) of the spin chain, the quasimomentum is restricted to \( k \in \{\pm \frac{\pi}{N}, \pm \frac{2\pi}{N}, \ldots, \pm \frac{\pi(N-1)}{N}\} \). In the following, we focus on the thermodynamic limit \( N \to \infty \), where we have \(-\pi \leq k \leq \pi \).

Even if we prepare the system initially in a ground state of the undriven model, under the effect of nonadiabatic external driving, the system will experience transitions to excited states. Rather recently, a formalism has been developed to deal with this kind of dynamical situations \([13, 25, 27]\). The idea is based on the fact that Hamiltonian Eq. \( \mathbf{1} \) conserves momentum and parity. As a consequence, we can use the BCS ansatz for the evolution of the quantum state of the system
\[
|\psi(t)\rangle = \bigotimes_{k>0} \left( u_k(t)|1-\nu, 1\rangle + v_k(t)|\nu, 0\rangle \right),
\]
which implies that for a given quasimomentum \( k \), the quantum evolution is restricted to the Nambu subspace \( \{|1-\nu, 1\rangle, |\nu, 0\rangle\} \), consisting of doubly occupied \( |1-\nu, 1\rangle \) and unoccupied \(|\nu, 0\rangle \) states of \( \pm k \) fermions \([26, 27, 41]\).

The matrix representation of the operator \( \hat{H}_k(t) \) in the Nambu subspace is given by
\[
H_k(t) = \left( \begin{array}{cc} \mu(t) - 2\omega_k & \Delta_k \\ -\Delta_k & -\mu(t) \end{array} \right),
\]
where \( H_k(t) \) is the Bogoliubov de Gennes (BdG) Hamiltonian, \( \omega_k = 2J \cos(k) \), \( \Delta_k = 2J \sin(k) \), and \( \mu(t) = 2g(t) \).

By defining the spinor \( \Psi_k(t) = (u_k(t), v_k(t))^t \), and considering the BCS ansatz Eq (5), it is possible to show that the coefficients \( u_k(t) \) and \( v_k(t) \) should satisfy the differential equation
\[
i \frac{d}{dt} \Psi_k(t) = H_k(t) \Psi_k(t),
\]
which constitutes the dynamical version of the Bogoliubov de Gennes equation \([25]\). At this point we have translated the many-body problem into the solution of the time-dependent Schrödinger equation for an effective two-level system.

Under periodic driving, the Floquet theorem states that the solution of Eq. \( \mathbf{7} \) can be written as
\[
\Psi_k(t) = A_+ e^{-i\varepsilon^{(+)k}t} \Phi_k^{(+)}(t) + A_- e^{-i\varepsilon^{(-)k}t} \Phi_k^{(-)}(t),
\]
where \( \Phi_k^{(\pm)}(t) \) denote the Floquet modes corresponding to the quasienergies \(-\Omega/2 \leq \varepsilon^{(\pm)k} \leq \Omega/2 \). Furthermore, in the extended Hilbert space \( R \otimes T \), where \( R \) is the Hilbert space of square integrable functions and \( T \) the space of time-periodic functions, the Floquet states satisfy the eigenvalue problem
\[
H_k \Phi_k^{(\lambda)}(t) = \varepsilon_k^{(\lambda)}(t) \Phi_k^{(\lambda)}(t),
\]
where \( \lambda \in \{+, -\} \), \( \mathcal{H}_k = H_k(t) - i \frac{\partial}{\partial t} \) is the Floquet Bogoliubov de Gennes (FBdG) Hamiltonian, \( \varepsilon_k^{(\lambda)} \) are the quasienergies, and the Floquet modes \( \Phi_k^{(\lambda)}(t+T) = \Phi_k^{(\lambda)}(t) \) have the same period \( T = 2\pi/\Omega \) as the external driving \([14, 22]\).

B. Resonance conditions

In the thermodynamic limit, the Ising model is characterized by an infinite set of collective excitations. Under the effect of an external driving, the possibility of
multiphotonic resonances arises \[19, 21, 22\]. To study such quantum resonances, let us consider the system in the absence of driving \(g_1 = 0\). In this case, the Floquet modes and the quasienergies become the stationary states \(\phi^\pm_k\) and the excitation spectrum \(\epsilon^\pm_k = -\omega_k \pm \epsilon_k\) of the undriven system, respectively \[21, 22\]. Therefore, the solution of Eq. (7) can be written in the form of Eq. (5) as follows

\[ \psi_k(t) = a^\pm e^{-i\epsilon^\pm_k t} \phi^\pm_k + a^\mp e^{-i\epsilon^\mp_k t} \phi^\mp_k. \] (10)

The energy gap is given by \(\Delta E_k = \epsilon^+_k - \epsilon^-_k = 2\epsilon_k\), where

\[ \epsilon_k = 2\sqrt{(g_0 - J \cos k)^2 + (J \sin k)^2}. \] (11)

In the semiclassical theory of light-matter interaction, we can interpret a Floquet state as a light-matter quantum state containing a definite, though very large, number of photons \[19\]. Multiple transitions between quantum states of the spin chain that are not directly coupled by the interaction can occur by means of intermediate states with a different number of photons present \[19, 21\]. In particular, \(m\)-photon transitions occur when the condition

\[ \Delta E_k = m\Omega, \] (12)

with integer \(m\) is satisfied. For a parametric oscillator with fundamental frequency \(\epsilon_k\), Eq. (12) is the usual resonance condition \[36\]. In Floquet theory, Eq. (12) implies the existence of a crossing between the single-particle energy levels \(\epsilon_k\) and \(-\epsilon_k\) when the energy spectrum is folded into the Brillouin zone \[19\]. Such a crossing occurs at the wave vector

\[ k_0 = \pm \arccos \left( \frac{g_0^2 + J^2 - (m\Omega)^2}{2g_0J} \right), \] (13)

where the resonance condition is fulfilled, as is depicted in Fig. 1(b). Fig. 1(a) depicts the energy dispersion relation of the undriven system and the dashed lines in Fig. 1(b), the corresponding folding of the energy spectrum into the first Brillouin zone \(-\Omega/2 \leq \epsilon_k \leq \Omega/2\). In this paper we focus on the weak spin-spin coupling limit \(g_0, \Omega \gg J\). In this limit the multiphoton resonance condition reads

\[ g_0 = \frac{m\Omega}{4}. \] (14)

Such resonance condition will be used in the next section to perform a description of the system based on an effective time-independent Hamiltonian which is valid for parameters close to a multiphoton resonant.

II. PHYSICS IN THE ROTATING FRAME

The dynamical BdG equations allow us to investigate the full quantum evolution of the driven system. As we are interested in the asymptotic quantum dynamics and the description of critical signatures, it is convenient to describe the dynamics of the system in a rotating frame. In the weak spin-spin interaction limit, it is possible to neglect the fast oscillations in the rotating frame, and a description of the system based on the description for time-independent systems is possible via an approximate effective Hamiltonian.

A. The rotating wave approximation and the effective Hamiltonian

Motivated by the \(m\)-photon resonance condition in the weak spin-spin coupling limit Eq. (14), we perform a description of the system based on the rotating wave approximation \[20\]. Let us perform a unitary transformation of Hamiltonian Eq. (1) into a convenient rotating frame via the unitary operator

\[ \hat{U}^{(m)}(t) = \exp \left( i\alpha_m(t) \sum_{i=1}^{N} \sigma_i^x \right) \prod_{k>0} \hat{U}^{(m)}_k(t) \]

\[ = \prod_{k>0} \exp \left[ -2i\alpha_m(t)(c_k^+ c_k + c_{-k}^- c_{-k} - 1) \right], \] (15)
where $\alpha_m(t) = m(\Omega/4)t + \frac{g_1}{2}\sin\Omega t$. In the rotating frame the dynamics is governed by the Hamiltonian $\hat{H}^{(m)}(t) = [\hat{U}^{(m)}(t)]^\dagger \hat{H}\hat{U}^{(m)}(t)$, where $\hat{H} = \hat{H}(t) - i\frac{\partial}{\partial t} = \sum_{k>0} \hat{H}_k = \sum_{k>0}(\hat{H}_k(t) - \frac{i}{\hbar}\hat{H}_k(t))$ is the Floquet Hamiltonian. The explicit form of this operator is given by

\begin{equation}
\hat{H}^{(m)}(t) = -\delta^{(m)} \sum_{i=1}^N \sigma_i^x - \frac{J}{2} \left(1 + \cos[4\alpha_m(t)]\right) \sum_{i=1}^N \sigma_i^z \sigma_{i+1}^z - \frac{J}{2} \left(1 - \cos[4\alpha_m(t)]\right) \sum_{i=1}^N \sigma_i^y \sigma_{i+1}^y + \frac{J}{2} \sin[4\alpha_m(t)] \sum_{i=1}^N \sigma_i^x \sigma_{i+1}^z,
\end{equation}

where the detuning $\delta^{(m)} = g_0 - m(\Omega/4)$ describes how far the system is from resonance, and $m$ is an integer that denotes the order of the multiphotonic resonance [19]. By using the identity

\begin{equation}
\exp(iz \sin\Omega t) = \sum_{l=-\infty}^{\infty} J_l(z) \exp(lit\Omega t),
\end{equation}

where $J_l(z)$ is the $l$th-order Bessel function [37], the Hamiltonian Eq. [16] can be written in the form

\begin{equation}
\hat{H}^{(m)}(t) = \sum_{n=-\infty}^{\infty} \hat{h}_n^{(m)} \exp(in\Omega t).
\end{equation}

In analogy with the standard RWA of quantum optics, we obtain an approximate Hamiltonian to describe the $m$th resonance by neglecting all the terms in $\hat{H}^{(m)}(t)$ with oscillatory time-dependence: $\hat{H}_m(t) \approx \hat{h}_n^{(m)}$. This approximation is valid as long as the condition

\begin{equation}
\delta^{(m)}, J\mathcal{J}_m \left(\frac{4g_1}{\Omega}\right) \ll \Omega
\end{equation}

holds [21]. Finally, we obtain the time-independent effective Hamiltonian

\begin{equation}
\hat{h}_0^{(m)} = -\delta^{(m)} \sum_{i=1}^N \sigma_i^x - \sum_{i=1}^N (J_z^{(m)} \sigma_i^z \sigma_{i+1}^z + J_y^{(m)} \sigma_i^y \sigma_{i+1}^y),
\end{equation}

where the parameters $J_z^{(m)} = \frac{1}{2}[1 + (-1)^m \mathcal{J}_m(\frac{4g_1}{\Omega})]$ and $J_y^{(m)} = \frac{1}{2}[1 - (-1)^m \mathcal{J}_m(\frac{4g_1}{\Omega})]$ denote effective anisotropies in the rotating frame. Interestingly, the effective Hamiltonian Eq. [20] corresponds to an exactly solvable model, i.e., it is unitarily equivalent to the XY anisotropic spin chain in a transverse field [38–40]. However, in our case, the anisotropies depend upon either the order $m$ of the resonance as well as the driving amplitude $g_1$. Therefore, the driving amplitude of the local field now plays the role of a new parameter that influences the criticality of the system.

B. Signatures of criticality in the rotating frame

Under the RWA, the Hamiltonian $\hat{h}_0^{(m)}$ and the Floquet Hamiltonian $\hat{H} = \hat{H}(t) - i\frac{\partial}{\partial t}$ are isospectral operators, which implies that the eigenvalues of the effective Hamiltonian correspond to the quasienergies. As we show in appendix B—similarly to the Ising model [1], after a Jordan-Wigner transformation, and a discrete Fourier transform, the Hamiltonian Eq. [20] can be written as follows

\begin{equation}
\hat{h}_0^{(m)} = \sum_{k>0} \left[2\delta^{(m)} - \omega_k(c_k^+ c_k + c_{-k}^+ c_{-k}) - 2\delta^{(m)}\right] + \sum_{k>0} (-1)^n \Delta_k \mathcal{J}_m \left(\frac{4g_1}{\Omega}\right) (c_k^+ c_{-k} + c_{-k}^+ c_k) = \sum_{k>0} \hat{h}_{0,k}^{(m)}.
\end{equation}

The matrix representation of $\hat{h}_{0,k}^{(m)}$ in the Nambu subspace is given by

\begin{equation}
\hat{h}_{0,k}^{(m)} = \left(\begin{array}{cc}
2\delta^{(m)} - 2\omega_k & (-1)^m \Delta_k \mathcal{J}_m \left(\frac{4g_1}{\Omega}\right) \\
(-1)^m \Delta_k \mathcal{J}_m \left(\frac{4g_1}{\Omega}\right) & -2\delta^{(m)}
\end{array}\right).
\end{equation}

The Hamiltonian Eq. [21] can be diagonalized via a Bogoliubov transformation

\begin{equation}
\hat{h}_0^{(m)} = \sum_{k>0} \varepsilon_{k,m} \left(\begin{array}{c}
\gamma_k^+ \\
\gamma_k
\end{array}\right),
\end{equation}

where

\begin{equation}
\varepsilon_{k,m} = 2\sqrt{(\delta^{(m)} - J\cos k)^2 + \left(J\mathcal{J}_m \left(\frac{4g_1}{\Omega}\right) \sin k\right)^2}.
\end{equation}

Furthermore, the quasienergies are defined (modulus $\Omega$) by the equation

\begin{equation}
\varepsilon_{k,m}^{(\pm)} = -\omega_k \pm \varepsilon_{k,m} + \frac{m\Omega}{2},
\end{equation}

as defined in Eq. [19]. The quasienergy gap in the fermion picture is given by $\Delta E_{k,m} = \varepsilon_{k,m}^{(+)} - \varepsilon_{k,m}^{(-)} = 2\varepsilon_{k,m}$. 

Therefore, when the gap closes—modulus Ω, the effective Hamiltonian exhibits a behavior which resembles the dynamics of a critical quantum system. The continuous lines in Fig. 1 (b) depict the quasienergy dispersion relation for \( g_1 \neq 0 \). We observe that the driving lifts the degeneracy giving rise to an anticrossing. Based on the well-known results for the time-independent XY model that we summarize in appendix B, we find that the system described by the effective Hamiltonian Eq. \( \Phi_{1,0} = 0 \) exhibits an effective nonequilibrium Ising-like QPT along the critical lines \( |\delta(m)| = J \), and a nonequilibrium anisotropic QPT along the lines where \( J_m (\frac{\Delta g}{\Omega}) = 0 \), as long as the condition \( |\delta(m)| < J \) holds. The gapless quasienergy excitation spectrum for parameters along the critical lines is as a direct consequence of coherent destruction of tunneling \( [23, 24] \), i.e., of the existence of a generalized parity symmetry in the extended Hilbert space \( \mathcal{R} \otimes \mathcal{T} \), where \( \mathcal{R} \) is the Hilbert space of square integrable functions and \( \mathcal{T} \) the space of time-periodic functions \( [22] \).

Figure 2 (a) depicts the character of the quasienergy excitation spectrum \( \pm \varepsilon_{k,m} \) for parameters in the ferromagnetic phase FMY, along the critical line, and in the ferromagnetic phase FMZ, respectively. Figure 2 (b) depicts the phase diagram for the nonequilibrium QPT in the neighborhood of the 2-photon resonance. The white zones in the phase diagram correspond to the effective paramagnetic phase and are defined by the inequality \( J < |\delta(m)| < |\delta_{\text{max}}(m)| \), for \( m = 2 \), where \( \delta_{\text{max}}(m) \) denotes the maximum detuning for which the RWA is still valid. The anisotropic transition is characterized by two ferromagnetic phases, i.e., for \( J_{z \alpha}(m) > J_y(m) \) the system is in a ferromagnetically-ordered phase along \( z \) direction FMZ, while it is the other way around in the FMY phase. In Fig. 2 (c) we plot the the effective asymmetries \( J_{z \alpha}(m) \) and \( J_y(m) \) as a function of the driving amplitude \( g_1 \) in the case of a 2-photon resonance.

III. PHYSICS IN THE LABORATORY FRAME

A. Quantum evolution of an initial paramagnetic state

As we previously mentioned, the eigenvalues of the effective Hamiltonian correspond to the quasienergies of the system. However, the corresponding eigenstates do not necessarily correspond to Floquet modes. In order to obtain the Floquet modes, one should apply a unitary transformation back into the laboratory frame. In so doing, the positive-quasienergy Floquet mode around the \( m \)-photon resonance in the Nambu subspace is given by

\[
\Phi_{k,m}^{(+)}(t) = e^{i(\frac{\Delta g}{\Omega} t)} U_k^{(m)}(t) \begin{pmatrix} \cos(\phi_{k,m}) \\ -\sin(\phi_{k,m}) \end{pmatrix} = \begin{pmatrix} e^{-i(2\Delta g(t) - \frac{\Delta g}{\Omega} t)} \cos(\phi_{k,m}) \\ -e^{i(2\Delta g(t) + \frac{\Delta g}{\Omega} t)} \sin(\phi_{k,m}) \end{pmatrix},
\]

and, correspondingly, the negative-quasienergy Floquet mode is given by

\[
\Phi_{k,m}^{(-)}(t) = e^{i(\frac{\Delta g}{\Omega} t)} U_k^{(m)}(t) \begin{pmatrix} \sin(\phi_{k,m}) \\ \cos(\phi_{k,m}) \end{pmatrix} = \begin{pmatrix} e^{-i(2\Delta g(t) - \frac{\Delta g}{\Omega} t)} \sin(\phi_{k,m}) \\ e^{i(2\Delta g(t) + \frac{\Delta g}{\Omega} t)} \cos(\phi_{k,m}) \end{pmatrix},
\]

where

\[
\tan(2\phi_{k,m}) = \frac{-(-1)^m \Delta g \ J_m (\frac{\Delta g}{\Omega})}{2\delta(m) - \omega_k}.
\]

Now, let us investigate the quantum evolution in the laboratory frame around the \( m \)-photon resonance when the system is initialized in a paramagnetic state of the un-
driven model with all the spin polarized along the $x$ axis

$$|\psi_m, 0\rangle = \bigotimes_{k > 0} |0_{-k}, 0_k\rangle. \quad (29)$$

Restricted to the Nambu subspace for a given $0 \leq k \leq \pi$, such an initial state corresponds to the spinor $\Psi_{k,m}^\dagger(0) = (u_{k,m}^\dagger(0), v_{k,m}^\dagger(0)) = (0, 1)$, whose quantum evolution is given by

$$\Psi_{k,m}(t) = U_k^{(m)}(t) \exp(-i\mathcal{H}_k t) \Psi_{k,m}(0) = -\sin(\phi_{k,m}) \Psi_{k,m}^{(+)}(t) + \cos(\phi_{k,m}) \Psi_{k,m}^{(-)}(t), \quad (30)$$

where $\Psi_{k,m}^{(\pm)}(t) = e^{-i\epsilon_{k,m}^\pm} \Phi_{k,m}^{(\pm)}(t)$ denote the Floquet states restricted to the Nambu subspace.

B. The Dynamics of the transverse magnetization

By using the exact quantum evolution of the initial paramagnetic state, we are able to calculate the dynamics of physical observables in the laboratory frame. The transverse magnetization $M_x(t)$ gives us information about the occurrence of a macroscopic polarization of the spins along the $x$ axis. Let us consider the expectation value $M_x(t) = \frac{1}{N} \langle \psi_m, t | \sum_{i=1}^{N} \sigma_i^x | \psi_m, t \rangle$ close to the $m$-th resonance,

$$M_x(t) = -\int_0^\pi \frac{dk}{\pi} \Psi_{k,m}^\dagger(t) \sigma^x(k) \Psi_{k,m}(t) = 1 - 2 \int_0^\pi \frac{dk}{\pi} \sin^2(\varepsilon_{k,m} t) \sin^2(2\phi_{k,m}), \quad (31)$$

where

$$\sigma^x(k) = \frac{1}{2} \partial_{\hat{g}_0} \mathcal{H}_k = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (32)$$

and $\mathcal{H}_k$ is the FBdG Hamiltonian Eq. (4). Fig. 3 depicts the dynamics of the magnetization in the thermodynamic limit calculated using RWA (black curve). In particular, Fig. 3(a) show the dynamics for parameters in the nonequilibrium paramagnetic phase and Fig. 3(b) for the ferromagnetic phase FMZ. We observe that in the paramagnetic phase the system exhibits a stationary state which corresponds to a polarized state along the local field direction. In contrast, for parameters corresponding to the ferromagnetic phase FMZ, the state is not totally polarized along this direction. The green curve in Fig. 3 depicts the result of exact numerical calculation (see appendix C) of the magnetization for a finite size system $N = 100$.

In this dynamical scenario the connection with criticality is not obvious. Rather, signatures of quantum criticality in the laboratory frame may appear in the asymptotic dynamics. Let us consider now the time evolution of the expectation value of a general observable

$$\mathcal{O}(t) = \langle \psi_m, t | \mathcal{O} | \psi_m, t \rangle = \int_0^\pi \frac{dk}{2\pi} \Psi_{k,m}^\dagger(t) \mathcal{O}_k \Psi_{k,m}(t). \quad (33)$$

In general, following the argument established in [33], it is possible to show that $\mathcal{O}(t) = \mathcal{O}_{\text{per}}(t) + \mathcal{O}_{\text{tr}}(t)$, where

$$\mathcal{O}_{\text{per}}(t) = \sum_{\lambda \in \{+,-\}} \int_0^\pi \frac{dk}{2\pi} |A_{\lambda}^2| \Phi_{k,m}(t)^\dagger \mathcal{O}_k \Phi_{k,m}(t) \quad (34)$$

is the periodic contribution to the expectation value, which correspond to synchronization with the external driving. Here we consider $A_+ = -\sin(\phi_{k,m})$ and $A_- = \cos(\phi_{k,m})$. Correspondingly,

$$\mathcal{O}_{\text{tr}}(t) = \int_0^\pi \frac{dk}{2\pi} \Re \left[ A_+ A_- e^{-2i\epsilon_{k,m} t} |\Phi_{k,m}(t)^{(+)}\rangle \langle \Phi_{k,m}(t)^{(-)} | \right]. \quad (35)$$

denotes the transient component, which decays to zero in the long-time limit as a consequence of destructive interference in time [32]. Therefore, the system tends to synchronize with the external control in the long-time limit. We conclude that in the asymptotic dynamics, the Flo-
FIG. 4: Cycle-averaged energy $\bar{H}_m^{(\pm)}$ as a function of the driving amplitude $g_1$. (a) For parameters in nonequilibrium paramagnetic phase ($\delta^{(m)} > J$), for $m = 2$, where $g_0/\Omega = 0.515$. (b) For parameters inside the ladder of ferromagnetic phases ($\delta^{(m)} < J$), for $m = 2$, where $g_0/\Omega = 0.505$. The insets depict the second derivative of the cycle-averaged energy as a function of the driving amplitude $g_1$. We have considered $J/\Omega = 0.01$.

quiet modes determine the quantum critical behaviour, as we discuss in the next section.

C. Cycle-averaged expectation values in Floquet eigenstates

We now define cycle-averaged expectation values of physical observables. In the case of a time-dependent Hamiltonian $\hat{H}(t)$, the energy is not conserved. Therefore, to describe signatures of the quantum phase transition in the laboratory frame we define the averaged energy $\bar{H}_m^{(\pm)}$ in the Floquet state $|\Psi_m^{(\pm)}(t)\rangle = \bigotimes_{k>0} |\Psi_{k,m}^{(\pm)}(t)\rangle$ as

$$\bar{H}_m^{(\pm)} = \frac{1}{T} \int_0^T dt \frac{1}{T} \int_0^\pi \frac{dk}{2\pi} \langle \Psi_{k,m}^{(\pm)}(t) \rangle \hat{H}_k(t) \Psi_{k,m}^{(\pm)}(t)$$

$$= \frac{1}{T} \int_0^T dt \frac{1}{T} \int_0^\pi \frac{dk}{2\pi} \left( \varepsilon_{k,m}^{(\pm)} + (\Phi_{k,m}^{(\pm)}(t))^\dagger i \frac{\partial}{\partial t} \Phi_{k,m}^{(\pm)}(t) \right).$$

By using the analytic expressions for the Floquet modes Eqs. (26) and (27) we obtain the expression

$$\bar{H}_m^{(\pm)} = \pm \int_0^\pi \frac{dk}{2\pi} \left( \varepsilon_{k,m} + \frac{m\Omega}{2} \cos(2\phi_{k,m}) \right).$$

On exact resonance $\delta^{(m)} = 0$, we obtain an analytical expression for the cycle averaged energy

$$\bar{H}_m^{(\pm)} = \frac{2J}{\pi} E \left[ 1 - \left( \mathcal{J}_m \frac{4g_1}{\Omega} \right)^2 \right],$$

where $E[z]$ is the complete elliptic integral of the second kind (see appendix B). This result confirms our prediction based on the description of the system in the rotating frame (see Fig. 2). The cycle-averaged energy exhibits singularities at the zeros of the Bessel function, i.e., $\mathcal{J}_m \left( \frac{4g_1}{\Omega} \right) = 0$. This is a clear signature of a critical nonequilibrium behaviour. Finally, we calculate the cycle-averaged transverse magnetization in the Floquet mode $|\Psi_m^{(\pm)}(t)\rangle$. By considering the extension of the Hellmann-Feynman theorem for Floquet theory [21,22], we can compute the cycle-averaged magnetization $\bar{M}_x^{(\pm)}$ in terms of derivatives of the quasienergies as follows

$$\bar{M}_x^{(\pm)} = - \int_0^\pi \frac{dk}{2\pi} \frac{\partial \varepsilon_{k,m}^{(\pm)}(t)}{\partial g_0} \frac{\partial}{\partial \phi_{k,m}} \Phi_{k,m}^{(\pm)}(t)$$

$$= - \int_0^\pi \frac{dk}{2\pi} \frac{\partial \varepsilon_{k,m}^{(\pm)}}{\partial g_0} = \mp \int_0^\pi \frac{dk}{\pi} \cos(2\phi_{k,m}).$$

Figures 4 and 5 show the cycle-averaged expectation values of observables. Similarly to the undriven case, the system exhibit nonanalyticities in the second derivative of observables—as can be seen in the corresponding insets, thus resembling a continuous phase transition. Such
nonanalyticities arise as a consequence of CDT [23, 24], and therefore, from the gapless quasienergy spectrum.

IV. CONCLUSIONS

We have investigated the nonequilibrium critical behaviour in a driven 1-dimensional transverse Ising model. We find that the fundamental signature of critical behaviour is the existence of a gapless quasienergy spectrum, which is a direct consequence of CDT. The role of coherent destruction of tunneling in nonequilibrium QPT has been explored either theoretically as experimentally in the context of driven superfluidity [12, 14]. In this paper, we show that CDT induces a critical behaviour which resembles a second order QPT. In particular, the symmetry which is broken corresponds to a generalized parity in an extended Hilbert space $\mathcal{R} \otimes \mathcal{T}$, where $\mathcal{R}$ is the Hilbert space of square integrable functions and $\mathcal{T}$ the space of time-periodic functions. In this nonadiabatic scenario, the short time dynamics is governed by transient effects that tend to zero in the asymptotic limit as a consequence of destructive interference [33]. The long time dynamic is governed by the Floquet modes, therefore, the nonequilibrium quantum phases correspond to states which are synchronized with the external control.

Possible experimental implementations of our model could be achieved using cold atoms [2, 3, 6], and in fully C-labelled sodium butyrate using liquid state nuclear magnetic resonance (NMR) [12, 43].

Appendix A: Description of the periodically-driven Ising model for finite size

In this section we introduce the fundamental tools used in the solution of the Ising model following the methods and the notation of reference [23].

Let us consider the Hamiltonian Eq. (1) in the case of even number of lattice sites $N$. For convenience, we use the Jordan-Wigner representation of the Pauli matrices

$$\sigma_j^x = 1 - 2c_j^\dagger c_j,$$
$$\sigma_j^y = -i(c_j^\dagger - c_j)\prod_{l=j}^{j-1}(1 - 2c_l^\dagger c_l),$$
$$\sigma_j^z = (c_j^\dagger + c_j)\prod_{l=j}^{j-1}(1 - 2c_l^\dagger c_l).$$

Under this representation of the angular momentum algebra, the parity operator Eq. (3) acquires the form

$$\hat{\Pi} = \prod_{j=1}^{N} (1 - 2c_j^\dagger c_j).$$

Using this parity operator we are able to define projectors on the subspaces with even (+) and odd (−) number of fermionic quasiparticles as follows

$$\hat{P}_\pm = \frac{1}{2} (1 \pm \hat{\Pi}).$$

The projectors $\hat{P}_\pm$ satisfy the usual properties of orthogonal projection operators such as $\hat{P}_+ + \hat{P}_- = 1$, $\hat{P}_+ \hat{P}_- = \hat{P}_- \hat{P}_+ = 0$, and $(\hat{P}_\pm)^2 = \hat{P}_\pm$. Using this properties and the algebra of fermionic operators is possible to show that the Hamiltonian Eq. (1) can be decomposed as follows

$$\hat{H}(t) = \hat{P}_+ \hat{H}^{(+)}(t) \hat{P}_+ + \hat{P}_- \hat{H}^{(−)}(t) \hat{P}_-, $$

where

$$\hat{H}^{(±)}(t) = -g(t) \sum_{i=1}^{N} (1 - 2c_i^\dagger c_i) - J \sum_{i=1}^{N} (c_i^\dagger - c_i)(c_{i+1}^\dagger + c_{i+1}).$$

To perform the splitting we have defined antiperiodic boundary conditions in the even (+) subspace $c_{N+1} = -c_1$ and periodic boundary conditions in the odd (−) subspace $c_{N+1} = c_1$. In this paper we focus on the projection $\hat{H}^{(+)}$ in the even subspace. Translational invariance suggest to use the discrete Fourier transform

$$c_n = \frac{e^{-in\pi/4}}{\sqrt{N}} \sum_k c_k e^{in\pi n},$$

which is compatible with the antiperiodic boundary conditions when $k \in \{ \pm \pi N, \pm 3\pi N, \ldots, \pm \frac{(N-1)\pi N}{N} \}$. The discrete Fourier transform maps $\hat{H}^{(+)}$ into Hamiltonian Eq. (2).

Appendix B: The quantum phase transition in the anisotropic XY spin chain in a transverse field

Here we consider the critical behaviour in a model described by the Hamiltonian

$$\hat{H} = -h \sum_{i=1}^{N} \sigma_i^x - \sum_{i=1}^{N} (J_x \sigma_i^x \sigma_{i+1}^x + J_y \sigma_i^y \sigma_{i+1}^y),$$

where...
which is unitarily equivalent to the Hamiltonian of an anisotropic XY spin chain in a transverse field [38–40].

Similarly to the Ising model, after Jordan-Wigner transformation, and a discrete Fourier transform, the Hamiltonian Eq. (B1) in the even subspace (the subspace with a even number of fermionic quasiparticles) acquires the form

\[
\hat{H} = \sum_{k>0} \left( 2 \left( h + (J_z + J_y) \cos k \right) (c_k^\dagger c_k + c_{-k}^\dagger c_{-k}) - 2h \right) + \sum_{k>0} 2(J_z - J_y) \sin k (c_k^\dagger c_{-k} + c_{-k}^\dagger c_k). \tag{B2}
\]

The diagonalization of this Hamiltonian is completed after a Bogoliubov transformation,

\[
\hat{H} = \sum_k E_k \left( \gamma_k^\dagger \gamma_k - \frac{1}{2} \right), \tag{B3}
\]

where

\[
E_k = 2\sqrt{(h - (J_z + J_y) \cos k)^2 + ((J_z - J_y) \sin k)^2}. \tag{B4}
\]

The system exhibits an Ising-like QPT along the lines \(|h| = J_z + J_y\) and an anisotropic QPT along the line \(J_z = J_y\), providing that \(|h| < J_z + J_y\). The anisotropic transition is characterized by two ferromagnetic phases, i.e., for \(J_z < J_y\) the system is in a ferromagnetically-ordered phase along z direction FMZ, while it is the other way around in the FMY phase. Similarly to reference [39], we consider a reparametrization of the asymmetries

\[
J_z = J / 2(1 + \gamma),
\]

\[
J_y = J / 2(1 - \gamma), \tag{B5}
\]

where \(\gamma\) is dimensionless parameter characterizing the degree of anisotropy in the \(zy\) plane. Under this reparametrization, the Ising-like critical lines correspond to \(|h| = J\), and the anisotropic transition occurs at \(\gamma = 0\), as long as \(|h| < J\).

Interestingly, in the absence of a transverse field, i.e., for \(h = 0\), the scaled ground-state energy can be written in the thermodynamic limit as

\[
E_G = -\lim_{N \to \infty} \frac{1}{N} \sum_k \frac{E_k}{2}
= -J \int_{-\pi}^{\pi} \frac{dk}{2\pi} \sqrt{1 - (1 - \gamma^2)} \sin^2 k
= -\frac{2J}{\pi} E[1 - \gamma^2]. \tag{B6}
\]

where \(E[z]\) is the complete elliptic integral of the second kind [37]. The scaled ground state energy exhibits a non-analyticity of the second derivative at the critical line of the anisotropic transition \(\gamma = 0\) [32], which is a generic characteristic of a second-order QPT [1].

Appendix C: Numerical calculation of the expectation values

By using the BCS ansatz Eq. (4) we can solve the Schrödinger equation for the Ising model in terms of the solution of the Schrödinger equation for an effective two-level system described by the BdG Hamiltonian Eq. (4), which is parametrized by the quasimomentum \(k \in \{\pm \frac{\pi}{4}, \pm \frac{3\pi}{4}, \ldots, \pm \frac{(N-1)\pi}{4}\}\). In the numerical calculation we assume that the system is prepared initially in the unoccupied state \(|0_{-k}, 0_k\rangle\), which implies that \(\Psi_{k}(0) = (u_{k}^\dagger(0), v_{k}^\dagger(0)) = (0, 1)\). After numerical integration of the dynamical BdG Eq. (7), we find the spinor \(\Psi_{k}(t)\). To calculate the scaled expectation value of the transverse magnetization \(M_x(t)\), we use the formula

\[
M_x(t) = -\frac{2}{N} \sum_{k>0} (\Psi_{k}(t))^\dagger [\sigma^z(k)] \Psi_{k}(t). \tag{C1}
\]

In the last expression we have used the definition of \(\sigma^z(k)\) given in Eq. (22). For example, to calculate the dynamics of the system for \(N = 4\), we perform the numerical integration of Eq. (4) for \(k \in \{\frac{\pi}{4}, \frac{3\pi}{4}\}\). Based on the solution of this equation we find the solution of the Schrödinger equation for Hamiltonian Eq. (1) using the BCS ansatz

\[
|\psi^\dagger, t\rangle = |\psi^\dagger, 0\rangle \otimes |\psi^\dagger, 0\rangle, \tag{C2}
\]

where

\[
|\psi^\dagger, 0\rangle = (u^\dagger_0(0)|1_{-\dagger}, 1_{\dagger}) + v^\dagger_0(0)|0_{-\dagger}, 0_{\dagger})\tag{C3}
\]

and

\[
|\psi^\dagger, t\rangle = (u^\dagger(t)|1_{-\dagger}, 1_{\dagger}) + v^\dagger(t)|0_{-\dagger}, 0_{\dagger})\tag{C4}
\]
